Bilateral discoid medial menisci: a rare phenomenon

Puspak Samal1, MS, Kishan Bhagwat1, MS, Tapas Panigrahi2, MS, Nirmalraj Gopinathan1, MS

INTRODUCTION

Discoid meniscus is an uncommon cause of internal derangement of the knee. The discoid-shaped meniscus mostly occurs on the lateral side of the knee joint. This anomaly very rarely occurs in the medial side, with the first of such a case reported by Cave and Staples in 1941.1 Discoid medial menisci in both knees (i.e. bilateral) is also rare.2 Since Murdoch reported the first case of bilateral discoid medial menisci in 1956,3 fewer than 20 cases have been reported in the literature.4 We herein report a case of bilateral discoid medial menisci with a tear on one side, which was successfully treated by arthroscopy.

CASE REPORT

A 25-year-old man presented with complaints of pain, recurrent swelling and occasional clicking of the right knee. He had an episode of a twisting injury to the knee while running on uneven surface one year earlier. The pain increased with walking for long distances, climbing stairs and squatting. It was also associated with recurrent episodes of knee joint effusion. Upon physical examination, quadriceps wasting and evidence of mild knee joint effusion were noted. Joint line tenderness and McMurray’s tests for medial meniscus injury were positive. The range of motion (ROM) was 0°–110° of flexion and terminal movements elicited pain in the patient’s right knee. There were no signs of instability in the knee joint, and the contralateral left knee was asymptomatic.

Standing anteroposterior and lateral radiography showed a widening of the medial joint space in both knees (Figs. 1 & 2) and increased cupping of the medial condyle of the tibia in the right knee. Magnetic resonance (MR) imaging of the right knee revealed the classic ‘bow tie’ appearance in three consecutive sagittal images and a continuity of meniscal material approaching the intercondylar area. There was a horizontal tear of the posterior horn of the meniscus. Based on these findings, the diagnosis of discoid medial meniscus with a horizontal tear was made (Fig. 3). The lateral meniscus was normal. Although the left knee was asymptomatic, we assessed it to exclude bilateralism. MR imaging revealed the presence of a variety of discoid medial meniscus with increased cupping of the medial condyle of the tibia (Fig. 4).

Arthroscopy of the symptomatic right knee confirmed the presence of discoid medial meniscus extending almost into the intercondylar area (Fig. 5a). Evidence of fatty degeneration was also seen around the intercondylar area and the posterior horn of the medial meniscus (Fig. 5b). The horizontal tear of the

Case Report

Posterior horn extended from the midsubstance (Fig. 5c). Other intra-articular structures were normal. Judicious partial resection of the torn part of the medial meniscus was performed (Fig. 5d). The patient was allowed full weight-bearing and knee movement from the first postoperative day. At follow-up two years later, the patient was doing well with complete painless ROM.

Discussion

Since the report by Cave and Staples in 1941, discoid medial meniscus still remains an uncommon clinical entity and bilateralism is exceedingly rare. The actual incidence of discoid medial meniscus and its bilateralism is difficult to cite because most patients are asymptomatic. Out of the 10,000 meniscectomies reported by Smillie, 467 were done for discoid lateral meniscus and 7 for discoid medial meniscus. In 14,731 meniscal injuries examined by Dikason et al., 10 out of 8,040 (0.12%) medial meniscal and 102 out of 6,691 (1.52%) lateral meniscal injuries were discoid. The reported incidence of discoid medial meniscus was 0.06%–0.30% in various studies.

The aetiology of discoid meniscus is controversial. In 1948, Smillie postulated that the discoid shape is normal in the developing embryo, and that failure of absorption of the central portion, which persists during the fetal stage, leads to ‘congenital discoid meniscus’. In 1974, Weiner and Rosenberg attributed discoid meniscus to congenital changes in the tibia. Stable discoid is often an incidental finding in asymptomatic patients. It can, however, be symptomatic in the presence of a tear, and the most common tear pattern is that of a degenerative horizontal cleavage, comprising 58%–98% of all symptomatic discoid menisci. Our patient had a large horizontal tear extending from the midsubstance to the posterior horn of the medial meniscus.

The radiological findings associated with discoid medial meniscus are: (a) cupping of the medial tibial plateau; (b) proximal tibial physis collapse; and (c) widening of the medial joint space. Atay et al reported a case where bilateral cupping of the medial tibial plateau was observed. In our case, there was bilateral widening of the medial joint space and an increased cupping of the medial condyles of the tibia.

MR imaging has facilitated the diagnosis of discoid meniscus. The presence of the ‘bow tie’ sign in more than three slices of sagittal plane MR images suggests the occurrence of discoid meniscus. In coronal plane MR imaging, the most accurate criterion for the diagnosis of discoid meniscus is when the ratio of the minimal meniscal width to the maximal tibial width is more than 20%. However, arthroscopy remains the gold standard for diagnosing discoid meniscus. According to the Watanabe classification, our case had a complete variety of...
discoid medial meniscus on the right knee. Fatty degeneration around the posterior horn of the medial meniscus, as seen in our patient, was also observed by Nam in his case report.\(^2\)

There are several types of anomalies associated with discoid medial meniscus, such as hypoplasia of the anterior horn, anomalous attachment of the posterior horn to the femoral condyle, and anomalous attachment to the anterior cruciate ligament;\(^{11,13}\) in our case, the rest of the intra-articular structures were normal.

Patel et al\(^{14}\) recommend that the discoid meniscus be preserved if severe symptoms are absent and advocate partial resection (i.e., saucerisation) of a torn symptomatic meniscus. In our case, we performed a partial meniscectomy until a stable peripheral rim was achieved. The patient was doing well at the two-year follow up. In general, the results of partial meniscectomy in discoid meniscus are good. However, only symptomatic cases should be treated surgically, as most cases of discoid meniscus remain asymptomatic.\(^{15}\)

In conclusion, discoid medial meniscus is a rare abnormality. Good quality radiography and MR imaging aid in preoperative diagnosis. MR imaging-assisted preoperative planning can provide surgeons with the opportunity to plan for partial resection so as to lessen the chance of early onset of osteoarthritis. Bilateralism should be ruled out in every case of discoid medial meniscus so that the patient can take precautions to avoid a similar injury in the contralateral asymptomatic limb in the future.
