ABSTRACT
We present five patients with vibrio necrotising fasciitis, a lethal and disabling disease. Among our patients, two had a history of exposure to either warm seawater or raw/live seafood, three had underlying chronic liver disease, and four presented with hypotension and fever. There were three deaths and four patients required intensive care unit stay. Among the survivors, one had high morbidity. Only one patient met the criteria of Laboratory Risk Indicator for Necrotizing Fasciitis score $> 6$. A clinician should suspect possible vibrio necrotising fasciitis if there is contact with fresh seafood/warm seawater, known history of chronic liver disease and pain out of proportion to cutaneous signs. All patients must be managed via intensive care in the high-dependency units. We recommend a two-step surgical protocol for patient management that involves an initial local debridement followed by a second stage radical debridement and skin grafting.

Keywords: LRINEC score, outcome, treatment, vibrio necrotising fasciitis
INTRODUCTION

*Vibrio vulnificus* (*V. vulnificus*) is a Gram-negative halophilic marine bacillus that is found in warm seawater, and on shellfishes and crustaceans. It proliferates in warm coastal environments. The number of patients diagnosed with vibrio necrotising fasciitis has been reported to be on the rise due to a rise in sea surface temperatures. This is especially relevant for Singapore, which is both warm and coastal. Despite increasing clinical awareness and advancements in antibiotic and infection management algorithms, vibrio necrotising fasciitis still remains a lethal and disabling disease. We report five patients with vibrio necrotising fasciitis treated at National University Hospital, Singapore, between 2005 and 2014 (Table I) and highlight pertinent points that could help to achieve a favourable treatment outcome in these patients.

CASE SERIES

Patient 1

A 61-year-old Malay woman, with a history of Child-Pugh class A hepatitis C virus liver cirrhosis and coronary artery disease, presented with a two-day history of severe left medial thigh pain and swelling that was associated with fever and tachycardia. She had no prior history of trauma or contact with seafood or seawater. On examination, her left thigh was swollen and extremely tender, with blistering and purple erythema. She underwent urgent magnetic resonance (MR) imaging of the left thigh, which showed increased STIR/T2 signal and free fluid in the fascial planes, which was suggestive of necrotising fasciitis (Fig. 1). However, the patient’s Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score was 3. Her blood and wound cultures were both positive for *V. vulnificus*. She underwent emergency left thigh debridement and fasciectomy, with intraoperative findings of ‘dishwater’ fluid and necrotic fascia. Postoperatively, she was admitted to the intensive care
unit (ICU), where her condition was complicated by acute renal failure and subsequent multiorgan failure. She was pronounced dead on Postoperative Day 5 despite maximal resuscitative efforts.

Patient 2
A 65-year-old Chinese man, with a history of poorly controlled diabetes mellitus, hypertension and hyperlipidaemia, presented with a two-day history of bilateral upper limb rash and blistering associated with fever after cleaning his boat. On examination, the patient was drowsy and hypotensive (blood pressure 78 mmHg/48 mmHg), and his right forearm was warm, tender and grossly indurated with blistering extending from the right forearm to the lateral aspect of the arm. He was unable to undergo MR imaging due to his unstable condition and was admitted to the ICU. His LRINEC score was 7. The patient was brought to the operation theatre for emergent right upper limb debridement and fasciectomy for suspected necrotising fasciitis, where the diagnosis of necrotising fasciitis was confirmed. His blood culture was positive for *V. vulnificus*. Over the next three months, he underwent multiple further wound debridement. His ICU stay was complicated by ventilator-associated pneumonia, acute respiratory distress syndrome and acute kidney injury, and the patient was discharged after three months.

Patient 3
A 53-year-old Chinese man who was a hepatitis B virus carrier, with a history of poorly controlled diabetes mellitus and multiple comorbidities, presented with a one-day history of left ankle and leg pain and swelling associated with fever. There was no history of contact with marine organisms or seawater. On examination, he was hypotensive (blood pressure 90 mmHg/60 mmHg) and remained so despite intravenous fluid resuscitation. His left ankle was
tender with progressively ascending blistering and erythema. His LRINEC score was 3. The patient underwent emergency fasciectomy (Fig. 2) and multiple lower limb debridement with subsequent skin grafting. His blood and wound cultures were both positive for *Vibrio cholerae*.

**Patient 4**

A 83-year-old Chinese man, with no significant past medical history, presented with a two-day history of pain and swelling of the dorsum of his left hand associated with fever, after getting pricked by a live crab. On examination, he had severe hypotension (blood pressure 57 mmHg/33 mmHg) and tachycardia. There was erythema, skin necrosis and blistering that extended up the dorsum of his hand to his olecranon. The puncture mark was visible with purulent discharge. His LRINEC score was 6. A diagnosis of necrotising fasciitis was made and the patient was managed with a left above-elbow amputation. His wound cultured positive for *V. vulnificus*. Postoperatively, he suffered an acute myocardial infarction complicated by acute renal failure and coagulopathy, which contributed to his demise despite maximal resuscitative efforts and inotropic support in the surgical ICU.

**Patient 5**

A 67-year-old Chinese woman, who was a hepatitis B virus carrier, presented with a three-day history of bilateral lower limb pain and swelling associated with fever. There was no history of trauma. On examination, she was hypotensive and tachypnoeic. Her bilateral lower limbs were erythematous, oedematous and blistering up to the level of her medial malleoli. Her LRINEC score was 4. She underwent multiple extensive debridement of her lower limbs, which confirmed the diagnosis of necrotising fasciitis, and her blood cultures were positive
for *V. vulnificus*. Despite full intensive care support, the patient’s condition progressively deteriorated and she died.

**DISCUSSION**

Vibrio necrotising fasciitis is a true surgical emergency. Its rapid progression and fulminant course may be related to pathogen-derived exotoxins and/or enzymes, which induce vascular permeability changes, systemic inflammatory reactions leading to multiorgan failure, septic shock and even death.\(^{(2)}\) Its fulminant clinical presentation has resulted in mortality rates being reported to be as high as 25%–100%.\(^{(3)}\)

Vibrio necrotising fasciitis has significant associations with warm seawater contact and contact with marine organisms. In a study by Tsai et al,\(^{(4)}\) 97% of patients had a significant history of contact with warm seawater or raw seafood. By comparison, in our study, only 2 (40.0%) of 5 patients had exposure to either warm seawater or raw/live seafood. Given the increasing incidence of vibrio skin and soft tissue infections, especially in coastal waters with high sea surface temperatures (such as Singapore), public health policies, such as proper storage of seafood between 0°C and 4°C, can reduce the number and pathogenicity of *Vibrio* spp. as well as its threat to public health.\(^{(5,6)}\)

A significant personal history of chronic liver disease has also been reported to be significantly associated with vibrio necrotising fasciitis.\(^{(7)}\) This is extremely relevant in Singapore, where the prevalence of hepatitis B virus carriers is 6% and 20%–30% of these patients are known to progress to liver cirrhosis and/or liver cancer.\(^{(8)}\) Tsai et al\(^{(4)}\) also cited in their study that 28% of patients with vibrio necrotising fasciitis had a history of hepatic dysfunction. In our series, 3 (60.0%) of 5 patients had underlying chronic liver disease – two were hepatitis B virus carriers and one had hepatitis C virus liver cirrhosis.
Vibrio necrotising fasciitis is known to have a fulminant clinical presentation\(^{2,3}\), a finding that was very evident in our series. Out of 5 patients, 4 (80.0\%) presented initially to the emergency department with hypotension (blood pressure < 90 mmHg/60 mmHg) – 1 (20.0\%), who was not hypotensive, was in impending shock reflected by resting tachycardia (heart beat > 110 beats per minute). All our patients had fever at presentation. The rapid deterioration in the clinical course of this disease reemphasises the importance of a high index of suspicion on the part of clinicians, early recognition of infection and prompt treatment.

In our series, the mortality rate was high, as 3 (60.0\%) of 5 patients did not survive the infection. A total of 4 (80.0\%) of 5 patients required ICU stay. Among patients who survived (i.e. two), one had high morbidity and required inpatient stay for 120 days. This patient (i.e. Patient 4) also underwent 15 surgical procedures ranging from wound debridement to an eventual right forearm amputation. The average number of procedures for patients with vibrio necrotising fasciitis in our series was 5.6 per patient and the mean hospital stay was 30.2 days.

Hong et al\(^1\) reported the management of a series of patients diagnosed with vibrio necrotising fasciitis complicated by septic shock initiation using a two-staged surgical protocol with simple incision and drainage followed by selective debridement and skin grafting. The mortality of vibrio necrotising fasciitis at their institution, which was in the range of 41.5\%–70.6\%, was brought down to 37.5\% using this two-staged surgical protocol. We followed a similar two-part surgical strategy that involved an initial local debridement of necrotic fascia and subcutaneous tissue followed by a second stage of repeated radical debridement and skin grafting. Such an approach may potentially reduce the mortality rate for patients with pre-existing surgical contraindications due to other medical conditions, such as coagulation disorders and shock.\(^1\)
The LRINEC score has been shown to be less reliable for diagnosing vibrio necrotising fasciitis. When Wong et al(7) proposed the LRINEC score for diagnosing necrotising fasciitis, they cited a positive predictive value of 92.0% when a cut-off LRINEC score > 6 was used. However, Chao et al,(2) who studied the validity of the LRINEC score for diagnosing vibrio necrotising fasciitis, found that the mean LRINEC score in patients with vibrio necrotising fasciitis was 3.3 (p < 0.0001). Similarly, Tsai et al(4) found that 89% of patients with vibrio necrotising fasciitis had a LRINEC score < 6. These findings are very similar to our series, where only one of five patients with vibrio necrotising fasciitis met the criteria of LRINEC score > 6.

In conclusion, for the prevention of vibrio-related necrotising fasciitis, proper storage of seafood at the correct temperatures must be strictly enforced and implemented to prevent the proliferation of bacteria. A high index of suspicion is required on the part of clinicians for the early diagnosis of vibrio necrotising fasciitis. Relevant indicators in the patient’s clinical history include contact with fresh seafood/warm seawater and a known medical history of chronic liver disease. Pain out of proportion to cutaneous signs is another important indicator that should be noted during physical examination. We recommend that all patients diagnosed with vibrio necrotising fasciitis be managed intensively in the high-dependency care units. In addition, we also advocate a two-step surgical protocol for the management of these patients that involves an initial local debridement, including excision of all necrotic fascia and subcutaneous tissue, followed by a second-stage of repeat radical debridement and skin grafting.

*F: female; LRINEC: Laboratory Risk Indicator for Necrotizing Fasciitis; M: male*
FIGURES

Fig. 1 Multiplanar MR image of the left thigh of Patient 1 shows extensive subcutaneous stranding and oedema with enhancement in the left thigh. STIR/T2 high signal suggests fluid within the deep/intermuscular fascial planes predominantly along the anterior and medial compartments of the left thigh. The scan also shows mild patchy deep/intermuscular fascial enhancement.
Fig. 2 Photograph shows left leg of Patient 3, which shows necrotic fascia and copious amounts of ‘dishwater’ fluid and pus.
